Abstract—When scheduling a directed acyclic graph (DAG) of tasks on computational platforms, a good trade-off between load balance and data locality is necessary. List-based scheduling techniques are commonly used greedy approaches for this problem. The downside of list-scheduling heuristics is that they are incapable of making short-term sacrifices for the global efficiency of the schedule. In this work, we describe new list-based scheduling heuristics based on clustering for homogeneous platforms. Our approach uses an acyclic partitioner for DAGs for clustering. The clustering enhances the data locality of the scheduler with a global view of the graph. Furthermore, since the partition is acyclic, we can schedule each part completely once its input tasks are ready to be executed. We present an extensive experimental evaluation showing the trade-offs between the granularity of clustering and the parallelism, and how this affects the scheduling. Furthermore, we compare our heuristics to the best state-of-the-art list-scheduling and clustering heuristics, and obtain better performance in cases with many communications.

Index Terms—List scheduling, clustering, partitioning, directed acyclic graphs, data locality, concurrency.

I. INTRODUCTION

Scheduling is one of the most studied areas of computer science. A large body of research deals with scheduling applications/workflows modeled as Directed Acyclic Graphs (DAGs), where vertices represent atomic tasks, and edges represent dependencies [13]. Among others, list-based scheduling techniques are the most widely studied and used techniques, mainly due to the ease of implementation and explanation of the progression of the heuristics [1], [9], [14], [16], [18], [19], [20], [21]. In list-based scheduling techniques, tasks are ordered based on some predetermined priority, and then are mapped and scheduled onto processors. Another widely used approach is clustering-based scheduling [10], [11], [17], [20], [21], [22], where tasks are grouped into clusters and then scheduled onto processors.

Almost all of the existing clustering-based scheduling techniques are based on bottom-up clustering approaches, where clusters are constructively built from the composition of atomic tasks and existing clusters. We argue that such decisions are local, and hence cannot take into account the global structure of the graph. Recently, we have developed one of the first multi-level acyclic DAG partitioners [8]. The partitioner itself also uses bottom-up clustering in its coarsening phase. However, it uses multiple levels of coarsening, and then it partitions the graph into two parts by minimizing the edge cut between the two parts. Then, in the uncoarsening phase, it refines the partitioning while it projects the solution found in the coarsened graph to finer graphs until it reaches to the original graph. This process can be iterated multiple times, using a constraint coarsening (where only vertices that were assigned to same part can be clustered), in order to further improve the partitioning. We hypothesize that clusters found using such a DAG partitioner are much more successful in putting together the tasks with complex dependencies, and hence in minimizing the overall inter-processor communication.

In this work, we use the realistic duplex single-port communication model, where at any point in time, each processor can, in parallel, execute a task, send one data, and receive another data. Because concurrent communications are limited within a processor, minimizing the communication volume is crucial to minimizing the total execution time, or makespan.

We propose several DAG partitioning-assisted list-based scheduling heuristics for homogeneous platforms, aiming at minimizing the makespan when the DAG is executed on a parallel platform. In our proposed schedulers, when scheduling to a system with $p$ processing units (or processors), the original task graph is first partitioned into $K$ parts (clusters), where $K \geq p$. Then, a list-based scheduler is used to assign tasks (not the clusters). Our scheduler hence uses list-based scheduler, but with one major constraint: all the tasks of a cluster will be executed by same processor. This is not the same as scheduling the graph of clusters, as the decision to schedule a task can be made before scheduling all tasks in a predecessor cluster. Our intuition is that, since the partition is done beforehand, the scheduler “sees” the global structure of the graph, and it uses this to “guide” the scheduling decisions. Since all the tasks in a cluster will be executed on the same processor, the execution time for the cluster can be approximated by simply the sum of the individual tasks’ weights (actual execution time can be larger due to dependencies to tasks that might be assigned to other processors). Here, we heuristically decide that having balanced clusters helps the scheduler to achieve load-balanced execution. The choice of the number of parts $K$ is a trade-off between data locality vs. concurrency. Large $K$ values may yield higher concurrency, but would potentially incur more inter-processor communication. At the extreme, each task is a cluster, where we have the maximum potential concurrency. However, in this case, one has to rely on list-based scheduler’s local decisions to improve data locality, and hence reduce inter-processor communication.
Our main contribution is to develop three different variants of partitioning-assisted list-based scheduler, taking different decisions about how to schedule tasks within a part. These variants run on top of two classical list-based schedulers: (1) BL-EST chooses the task with largest bottom-level first (BL), and assigns the task on the processor with the earliest start time (EST), while (2) ETF tries all ready tasks on all processors and picks the combination with the earliest EST first (hence with a higher complexity). Also, we experimentally evaluate the new algorithms against the two baseline list-based schedulers (BL-EST and ETF) and one baseline cluster-based scheduler (DSC-GLB-ETF), since ETF and DSC-GLB-ETF are the winners of the recent comparison done by Wang and Sinnen [20]. However, unlike [20], we follow the realistic duplex single-port communication model. We show significant savings in terms of makespan, in particular when the communication-to-computation ratio (CCR) is large, i.e., when communications matter a lot, hence demonstrating the need for a partitioning-assisted scheduling technique.

The rest of the paper is organized as follows. First, we discuss related work in Section II. Next, we introduce the model and formalize the optimization problem in Section III. The proposed scheduling heuristics are described in Section IV, and they are evaluated through extensive simulations in Section V. Finally, we conclude and give directions for future work in Section VI.

II. RELATED WORK

Task graph scheduling has been the subject of a wide literature, ranging from theoretical studies to practical ones. Kwok and Ahmad [13] give an excellent survey and taxonomy of task scheduling methods and some benchmarking techniques to compare these methods [12].

DAG scheduling heuristics can be divided into two groups with respect to whether they allow task duplication or not [2]. Those that allow task duplication do so to avoid communication. The focus of this work is non-duplication based scheduling. There are two main approaches taken by the non-duplication based heuristics: list scheduling and cluster-based scheduling. A recent comparative study [20] gives a catalog of list-scheduling and cluster-scheduling heuristics and compares their performance.

In the list-based scheduling approach [1], [9], [14], [16], [18], [19], [21], each task in the DAG is first assigned a priority. Then, the tasks are sorted in descending order of priorities, thereby resulting in a priority list. Finally, the tasks are scheduled in topological order, with the highest priorities first. The list-scheduling based heuristics usually have low complexity and are easy to implement and understand.

In the cluster-based scheduling approach [10], [11], [17], [20], [21], [22], the tasks are first divided into clusters, each to be scheduled on the same processor. The clusters usually consist of highly communicating tasks. Then, the clusters are scheduled onto an unlimited number of processors, which are finally combined to yield the available number of processors.

Our approach is close to cluster-based scheduling in the sense that we first partition tasks into $K \geq p$ clusters, where $p$ is the number of available processors. At this step, we enforce somewhat balanced clusters. In the next step, we schedule tasks as in the list-scheduling approach, not the clusters, since there is a degree of freedom in scheduling a task of a cluster. Hence, our approach can also be conceived as a hybrid list and cluster scheduling, where the decisions of the list-scheduling part are constrained by the cluster-scheduling decisions.

We consider homogeneous computing platforms, where the processing units are identical and communicate through a homogeneous network. Task graphs and scheduling approaches can also be used to model and execute workflows on grids and heterogeneous platforms [5], [7]; HEFT [19] is a common approach for this purpose. Assessing the performance of our new scheduling strategies on heterogeneous platforms will be considered in future work.

III. MODEL

Let $G = (V, E)$ be a directed acyclic graph (DAG), where the vertices in the set $V$ represent tasks, and the edges in the set $E$ represent the precedence constraints between those tasks. Let $n = |V|$ be the total number of tasks. We use $\text{Pred}[v_i] = \{v_j \mid (v_j, v_i) \in E\}$ to represent the (immediate) predecessors of a vertex $v_i \in V$, and $\text{Succ}[v_i] = \{v_j \mid (v_i, v_j) \in E\}$ to represent the (immediate) successors of $v_i$ in $G$. Vertices without any predecessors are called source nodes, and the ones without any successors are called target nodes. Every vertex $v_i \in V$ has a weight, denoted by $w_i$, and every edge $(v_i, v_j) \in E$ has a cost, denoted by $c_{i,j}$.

The computing platform is a homogeneous cluster consisting of $p$ identical processing units, called processors, and denoted $P_1, \ldots, P_p$, communicating through a fully-connected homogeneous network. Each task needs to be scheduled onto a processor respecting the precedence constraints, and tasks are non-preemptive and atomic: a processor executes a single task at a time. For a given mapping of the tasks onto the computing platform, let $\mu(i)$ be the index of the processor on which task $v_i$ is mapped, i.e., $v_i$ is executed on the processor $P_{\mu(i)}$. For every vertex $v_i \in V$, its weight $w_i$ represents the time required to execute the task $v_i$ on any processor. Furthermore, if there is a precedence constraint between two tasks mapped onto two different processors, i.e., $(v_i, v_j) \in E$ and $\mu(i) \neq \mu(j)$, then some data must be sent from $P_{\mu(i)}$ to $P_{\mu(j)}$, and this takes a time represented by the edge cost $c_{i,j}$.

We enforce the realistic duplex single-port communication model, where at any point in time, each processor can, in parallel, execute a task, send one data, and receive another data. Consider the DAG example in Figure 1, where all execution times are unitary, and communication times are depicted on the edges. The computing platform in the example of Figure 1 has two identical processors. There is no communication cost to pay when two tasks are executed on the same processor, since the output can be directly accessed in the processor memory by the next task. For the proposed schedule, $P_1$ is already
performing a send operation when \( v_5 \) would like to initiate a communication, and hence this communication is delayed by 0.5 time unit, since it can start only after \( P_1 \) has completed the previous send from \( v_1 \) to \( v_2 \). However, \( P_1 \) can receive data from \( v_2 \) to \( v_3 \) in parallel to sending data from \( v_5 \) to \( v_6 \). In this example, the total execution time, or makespan, is 6.

Formally, a schedule of graph \( G \) consists of an assignment of tasks to processors (already defined as \( \mu(i) \), for \( 1 \leq i \leq n \)), and a start time for each task, \( st(i) \), for \( 1 \leq i \leq n \). Furthermore, for each precedence constraint \((v_i,v_j) \in E\) such that \( \mu(i) \neq \mu(j) \), we must specify the start time of the communication, \( com(i,j) \). Several constraints must be met to have a valid schedule, in particular with respect to communications:

- (atomicity) For each processor \( P_k \), for all tasks \( v_i \) such that \( \mu(i) = k \), the intervals \([st(i), st(i) + w_i]\) are disjoint.
- (precedence constraints, same processor) For each \((v_i,v_j) \in E\) with \( \mu(i) = \mu(j) \), \( st(i) + w_i \leq st(j) \).
- (precedence constraints, different processors) For each \((v_i,v_j) \in E\) with \( \mu(i) \neq \mu(j) \), \( st(i) + w_i \leq com(i,j) \) and \( com(i,j) + c_{i,j} \leq st(j) \).
- (one-port, sending) For each \( P_k \), for all \((v_i,v_j) \in E\) such that \( \mu(i) = k \) and \( \mu(j) \neq k \), the intervals \([com(i,j), com(i,j) + c_{i,j}]\) are disjoint.
- (one-port, receiving) For each \( P_k \), for all \((v_i,v_j) \in E\) such that \( \mu(i) \neq k \) and \( \mu(j) = k \), the intervals \([com(i,j), com(i,j) + c_{i,j}]\) are disjoint.

The goal is then to minimize the makespan, that is the maximum execution time:

\[
M = \max_{1 \leq i \leq n} \{st(i) + w_i\}.
\]

We are now ready to formalize the Minmakespan optimization problem: Given a weighted DAG \( G = (V, E) \) and \( p \) identical processors, the Minmakespan optimization problem consists in defining \( \mu \) (task mapping), \( st \) (task starting times) and \( com \) (communication starting times) so that the makespan \( M \) defined in Equation (1) is minimized.

Note that this classical scheduling problem is NP-complete, even without communications, since the problem with \( n \) weighted independent tasks and \( p = 2 \) processors is equivalent to the 2-partition problem [6].

Figure 1: Example of a small DAG with seven vertices executed on a homogeneous platform with two processors.

IV. ALGORITHMS

We propose novel heuristic approaches to solve the Minmakespan problem, using a recent directed graph partitioner [8]. We compare the results with classical list-based and clustering heuristics, that we first describe and adapt for the duplex single-port communication model (Section IV-A). Next, we introduce three variants of partition-assisted list-based scheduling heuristics in Section IV-B.

A. State-of-the-art scheduling heuristics

We first consider the best alternatives from the list-based and clustering heuristics presented by Wang and Sinnen [20]. We consider one static list-scheduling heuristic (BL-EST), the best dynamic priority list-based scheduling heuristic for real application graphs (ETF), and the best cluster-based scheduling heuristic (DSC-GLB-ETF).

a) BL-EST: This simple heuristic maintains an ordered list of ready tasks, i.e., tasks that can be executed since all their predecessors have already been executed. Let \( Ex \) be the set of tasks that have already been executed, and let \( Ready \) be the set of ready tasks. Initially, \( Ex = \emptyset \), and \( Ready = \{v_i \in V \mid Pred[v_i] = \emptyset\} \). Once a task has been executed, new tasks may become ready. At any time, we have:

\[
Ready = \{v_i \in V \mid Extended[Ex] = \emptyset \land \forall (v_j,v_i) \in E, v_j \in Ex\}.
\]

In the first phase, tasks are assigned a priority, which is designated to be its bottom level (hence the name BL). The bottom level \( bl(i) \) of a task \( v_i \in V \) is defined as the largest weight of a path from \( v_i \) to a target node (vertex without successors), including the weight \( w_i \) of \( v_i \), and all communication costs. Formally,

\[
bl(i) = w_i + \begin{cases} 
0 & \text{if } Succ[v_i] = \emptyset; \\
\max_{v_j \in Succ[v_i]} c_{i,j} + bl(j) & \text{otherwise}. 
\end{cases}
\]

In the second phase, tasks are assigned to processors. At each iteration, the task of the Ready set with the highest priority is selected and scheduled on the processor that would result in the earliest start time of that task. The start time depends on the time when that processor becomes available, the communication costs of its input edges, and the finish time of its predecessors. We keep track of the finish time of each processor \( P_k \) (\( \text{comp}_k \)), as well as the finish time of sending (\( \text{send}_k \)) and receiving (\( \text{recv}_k \)) operations. When we tentatively schedule a task on a processor, if several communications are needed (meaning that at least two predecessors of the task are mapped on other processors), they cannot be performed at the same time with the duplex single-port communication model. The communications from the predecessors are, then, performed as soon as possible (respecting the finish time of the predecessor and the available time of the sending and receiving ports) in the order of the finish time of the predecessors.

This heuristic is called BL-EST, for Bottom-Level Earliest-Start-Time, and is described in Algorithm 1. The Ready set
is stored in a max-heap structure for efficiently retrieving the tasks with the highest priority, and it is initialized at lines 1-5. The computation of the bottom levels for all tasks (line 1) can easily be performed in a single traversal of the graph in $O(|V| + |E|)$ time, see for instance [13]. The main loop traverses the DAG and tentatively schedules a task with the largest bottom level on each processor in the loop lines 11-20. The processor with the earliest start time is then saved, and all variables are updated on lines 24-29. When updating $\text{comp}(j,i)$, if $v_i$ and its predecessor $v_j$ are mapped on the same processor, communication start time is artificially set to $st(j) + w_j - c_{j,i}$ in line 25, so that $st(i)$ can be computed correctly in line 29. Finally, the list of ready tasks is updated in line 31, i.e., $Ex \leftarrow Ex \cup \{v_i\}$, and new ready tasks according to Equation (2) are inserted into the max-heap.

The total complexity of Algorithm 1 is hence $O(p^2|V| + |V| \log |V| + p|E|)$; $O(2^2|V|)$ for lines 11-13, $|V| \log |V|$ for the heap operations (we perform $|V|$ times the extraction of the maximum, and the insertion of new ready tasks into the heap), and $p|E|$ for lines 15-20. The BL-EST heuristic will be used as a comparison basis in the rest of this paper.

b) ETF: We also consider a dynamic priority list scheduler, ETF. For each ready task, this algorithm computes the earliest start time (EST) of the task. Then, it schedules the ready task with the earliest EST, hence the name ETF, for Earliest EST First. Since we tentatively schedule each ready task, the complexity of ETF is higher than BL-EST; it becomes $O(p^2|V|^2 + p|V||E|)$.

c) DSC-GLB-ETF: The clustering scheduling algorithm used as a basis for comparison is one of the best ones identified by Wang and Sinnen [20], namely, the DSC-GLB-ETF algorithm. It uses dominant sequence clustering (DSC), then merges clusters with guided load balancing (GLB), and finally orders tasks using earliest EST first (ETF). We refer the reader to [20] for more details about this algorithm.

B. Partition-based heuristics

The partition-based heuristics start by computing an acyclic partition of the DAG, using a recent DAG partitioner [8]. This acyclic DAG partitioner takes a DAG with vertex and edge weights, a number of parts $K$, and an allowable imbalance parameter $\varepsilon$ as input. Its output is a partition of the vertices of $G$ into $K$ nonempty pairwise disjoint and collectively exhaustive parts satisfying three conditions: (i) the weight of the parts are balanced, i.e., each part has a total vertex weight of at most $(1 + \varepsilon) \sum_{v \in V} w_v / K$; (ii) the edge cut is minimized; (iii) the partition is acyclic; in other words, the inter-part edges between the vertices from different parts should preserve an acyclic dependency structure among the parts. We use this tool to partition the task graph into $K = \alpha \times p$ parts, hence $\alpha \geq 1$ can be interpreted as the average number of clusters per processor. We choose an imbalance parameter of $\varepsilon = 1.1$ to have relatively balanced clusters; other values of $\varepsilon$ led to similar results. In this paper, we use the recommended version of the approach in [8], namely CoHyb_CIP.

\begin{algorithm}[h]
\caption{BL-EST algorithm}
\textbf{Data:} Directed graph $G = (V, E)$, number of processors $p$
\textbf{Result:} For each task $v_i \in V$, allocation $\mu(i)$ and start time $st(i)$; For each $(v_i, v_j) \in E$, start time $\text{comp}(j,i)$

\IF{$\mu(j) = k$}
\STATE $t \leftarrow st(j) + w_j$
\ELSE
\STATE $t \leftarrow c_{j,i} + \max(st(j) + w_j, \text{send}_{\mu(j)}(i), \text{recv}_k) - \text{send}_{\mu(j)}(i) \leftarrow \text{recv}_k \leftarrow t$
\ENDIF
\STATE $\text{begin}_k \leftarrow \max(\text{begin}_k, t)$
\ENDIF
\STATE $k^* \leftarrow \text{argmin}_k \{\text{begin}_k\}$ \quad \text{\textit{\# Best Processor}}
\STATE $\mu(i) \leftarrow k^*$
\STATE $st(i) \leftarrow \text{comp}_k$
\FOR{$v_j \in \text{Pred}[v_i]$}
\IF{$\mu(j) = k^*$}
\STATE $\text{comp}(j,i) \leftarrow \max(st(j) + w_j, \text{send}_{\mu(j)}(i), \text{recv}_{k^*})$
\STATE $\text{send}_{\mu(j)}(i) \leftarrow \text{recv}_{k^*} \leftarrow \text{comp}(j,i) + c_{j,i}$
\ELSE
\STATE $st(i) \leftarrow \max(st(i), \text{comp}(j,i) + c_{j,i})$
\ENDIF
\STATE $\text{comp}_k \leftarrow st(i) + w_i$
\ENDFOR
\STATE Insert new ready tasks into Ready
\end{algorithmic}
\end{algorithm}

Given $K$ parts $V_1, \ldots, V_K$ forming a partition of the DAG, we propose three variants of scheduling heuristics. Note that the variants are designed on top of BL-EST and ETF, but they can easily be adapted to any other list-based scheduling algorithm since, in essence, these heuristics are capturing a hybrid approach between cluster-based and list-based scheduling algorithms using DAG partitioning.

a) BL-EST-PART and ETF-PART: The first variant is used on top of BL-EST or ETF. The BL-EST-PART heuristic (resp. ETF-PART) performs a list scheduling heuristic similar to BL-EST described in Algorithm 1 (resp. similar to ETF), but with the additional constraint that two tasks that belong to the same part must be mapped on the same processor. This means that once a task of a part has been mapped, we enforce that other tasks of the same part share the same processor, and hence do not incur any communication cost among the tasks of the
same part. The pseudo-code of BL-EST-PART can be found in the companion research report [15], and the complexity of BL-EST-PART (resp. ETF-PART) is the same as BL-EST (resp. ETF). This variant is denoted *-PART (BL-EST-PART or ETF-PART).

b) BL-EST-BUSY and ETF-BUSY: One drawback of the *-PART heuristics is that it may happen that the next ready task is in a part that we are just starting (say $V_l$), while some other parts have not been entirely scheduled. For instance, if processor $P_i$ has already started processing a part $V_l$, but has not scheduled all of the tasks of $V_l$, yet, *-PART may decide to schedule the new task from $V_l$ onto the same processor if it will start at the earliest time. This may overload the processor and delay other tasks from both $V_l$ and $V_l$.

The second variant, BL-EST-BUSY (resp. ETF-BUSY), checks whether a processor is already busy with an on-going part, and it does not allocate a ready task from another part to a busy processor, unless if all processors are busy. In this latter case, BL-EST-BUSY behaves similar to BL-EST-PART (and ETF-BUSY behaves similar to ETF-PART). The pseudo-code of BL-EST-BUSY can be found in the companion research report [15], and the complexity of this variant is the same as BL-EST (resp. ETF).

c) BL-EFT-MACRO: The last heuristic, BL-EFT-MACRO, further focuses on the parts, and schedules a whole part before moving to the next one, so as to avoid problems discussed earlier. This heuristic relies on the fact that the partitioning is acyclic, and hence it is possible to process parts one after another in a topological order. Rather than considering EST, we consider here the Earliest Finish Time (EFT) of a part (see below), hence the name.

We extend the definition of ready tasks to parts. A part is ready if all its predecessor parts have already been processed. We also extend the definition of bottom level to parts, by taking the maximum bottom level of parts.

BL-EFT-MACRO is detailed in Algorithm 2. The algorithm selects the ready part with the maximum bottom level (using a max-heap for ready parts, ReadyParts), and tentatively schedules the whole part on each processor (lines 15–26). Tasks within the part are scheduled by non-increasing $bl(i)$’s, hence respecting dependencies. Incoming communications are scheduled at that time to ensure the single-port model, and outgoing communications are left for later. The processor that minimizes the finish time is selected, and the part is assigned to this processor. The finish times for computation, sending, and receiving are updated. Once a part has been scheduled entirely, the list of ready parts is updated, and the next ready part with the largest bottom level is selected. This heuristic has the same complexity as Algorithm 1.

V. SIMULATION RESULTS

We first describe the simulation setup in Section V-A, in particular, the different instances that we use in the simulations. Next, we compare the baseline algorithms under different communication models (communication-delay model vs. realistic model) in Section V-B. Section V-C shows the impact of the number of parts used by the partitioner, the communication-to-computation ratio (CCR), and the number of processors. Finally, we present detailed simulation results in Section V-D.

A. Simulation setup

The experiments were conducted on a computer equipped with dual 2.1 GHz Xeon E5-2683 processors and 512GB

In order to create instances with a target CCR, we proceed in two steps: (i) we first randomly assign costs and weights between 1 and 10 to each edge and vertex, and then (ii) we scale the edge costs appropriately to yield the desired CCR.

Since the ETF algorithms have a complexity in \(O(p^2|V|^2 + p|V||E|)\), they are not suited to million-node graphs that are included in the OCR and UFL datasets. Hence, we have selected a subset of OCR and UFL graphs, namely, graphs with 10k to 150k nodes, denoted as the medium dataset. The big dataset contains all graphs from Tables I and II.

### B. Communication-delay model vs. realistic model

Our goal is to compare the new heuristics with the best competitors from the literature [20]. We call them the baseline heuristics, as they represent the current state-of-the-art. We have access to executables of the original implementation [20]. However, these heuristics assume a pure communication delay model, where communications can all happen at the same time, given that the task initiating the communications has finished its computation. Hence, there is no need to schedule the communications in this model.

In our work, we have assumed a more realistic, duplex single-port communication model. Thus, we cannot directly compare the new heuristics with the executables of the baseline heuristics. We have, therefore, implemented our own version of the baseline algorithms (BL-EST, ETF as best list-based and DSC-GLB-ETF as best cluster-based scheduler) with the communication delay model, and compared the resulting makespans with those of Wang and Sinnen’s implementation, denoted as “ETF [W&S]”, in an attempt to validate our implementations. We show the performance profiles in Figure 2 for this comparison. In the performance profiles, we plot the percentages of the instances in which a scheduling heuristic obtains a makespan on an instance that is no larger than \(\theta \) times the best makespan found by any heuristic for that instance [4]. Therefore, the higher a profile at a given \(\theta\), the better a heuristic is. Results on Figure 2 confirm those presented by Wang and Sinnen: with low CCR (CCR=0.1 or CCR=1), DSC-GLB-ETF is worse than ETF (the higher the better). However, when the CCR increases, the performance of DSC-GLB-ETF also increases, and it surpasses ETF for CCR=10 at the end [20].

Figure 2 also shows that our implementation of ETF performs better than ETF [W&S]. This may be due to tie-breaking in case of equal ordering condition, that we could not verify in detail since we had only the executables. Our implementation ETF is, thus, a fair competitor, since it turns out to be better than the existing implementation.

Next, we converted our implementation of these algorithms into duplex single-port model, as explained in Section IV, in order to establish the baseline to compare the proposed heuristics. Figure 3 shows the performance profiles of our three baseline heuristics on the small dataset. From these results, we see that DSC-GLB-ETF is not well suited for the realistic communication model, since it performs pretty badly

---

Figure 2: Performance profiles comparing our implementation of baseline heuristics with Wang and Sinnen’s implementation of ETF, on the small data set, with the communication-delay model.

Figure 3: Performance profiles comparing baselines on the small dataset, with the duplex single-port communication model.

Figure 4: Relative makespan compared to BL-EST on the big dataset, as a function of the number of parts, with CCR=10 and with 2 (top left), 4 (top right), 8 (middle left), 16 (middle right), and 32 (bottom left) processors.

Figure 5: Relative makespan compared to BL-EST on the big dataset, as a function of the CCR, with 2 (top left), 4 (top right), 8 (middle left), 16 (middle right), and 32 (bottom left) processors.

In comparison to ETF, BL-EST is also slightly worse than ETF, but it has a lower theoretical complexity.

C. Impact of number of parts, processors, and CCR

In this section, we evaluate the impact of number of parts in the partitioning phase, number of processors, and CCR of datasets, on the quality of the proposed heuristics.

Figure 4 depicts the relative performance of BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO compared to BL-EST on the big dataset as a function of $\alpha$ for different number of processors, $p = \{2, 4, 8, 16, 32\}$, and CCR=10. We set the number of parts $K = \alpha \times p$ and we have $\alpha = \{1, 2, 3, 4, 6, 8, 10, 12, 14, 16\}$. As seen in the figure, except BL-EFT-MACRO on $p = 32$ processors, the new algorithms perform better than the baseline BL-EST for all values of $\alpha$ that we tested. Even for the worst case, that is, on 32 processors, BL-EFT-MACRO performs better or comparable to BL-EST, when $\alpha \leq 4$. Therefore, we recommend to select $\alpha \leq 4$.

As shown in the previous studies (e.g., [20]), performance of the scheduling algorithms vary significantly with different CCRs, and in particular, clustering-based schedulers perform
better for high CCRs. Figure 5 shows the performance of the heuristics on the big dataset with varying CCR, i.e., for CCR={1, 5, 10, 20} and for p = {2, 4, 8, 16, 32}. As expected, similar to existing clustering-based schedulers, the proposed heuristics give significantly better results than the BL-EST baseline. For instance, when CCR=20, for all numbers of processors in the figure, all partitioning-based heuristics give at least 50% better makespans.

Comparing the relative performance of BL-EST-PART and BL-EST-BUSY across the sub-figures, one observes that BL-EST-PART and BL-EST-BUSY have more or less stable performance with the increasing number of processors. Note that the performance of BL-EST-PART and BL-EST-BUSY mostly depends on the value of CCR, but remains the same when the number of processors varies. BL-EST-MACRO performs worse than the other two heuristics for small values of CCR with an increasing number of processors. However, for tested values of p, the performance of BL-EST-MACRO improves as the CCR increases, and finally it outperforms all other heuristics on average when the CCR is large enough.

D. Runtime comparison and performance results

We present the results on the small, medium and big datasets. We focus only on the BL-EST algorithm for the big dataset, since ETF does not scale well, and DSC-GLB-ETF shows poor results with the realistic communication model and smaller datasets. Let us consider XSBench graph as an example of how long it takes to run ETF on one of the big graphs. When we schedule this graph on two processors, the DAG partitioning algorithm runs in 9.5 seconds on average, and BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO heuristics run under half a second to totalize approximately 10 seconds. However, ETF algorithm takes 4759 seconds. On four processors, it goes up to 7507 seconds.

a) Small dataset: Figure 6 shows the comparison of all heuristics on the small dataset for CCR={0.1, 1, 10}. While ETF remains the best with a small CCR=0.1, the new heuristics become better as soon as CCR=1, where ETF-PART, ETF-BUSY, and BL-EFT-MACRO behave very well. Finally, the performance of BL-EFT-MACRO is striking for CCR=10, where it clearly outperforms all other heuristics.

As seen before, DSC-GLB-ETF performs poorly in this case, due to the realistic communication model.

b) Medium dataset: Figure 7a shows the performance profile for the medium dataset. As expected, dynamic scheduling technique ETF and our ETF-based heuristics perform better than their BL-EST counterparts, as for the small dataset. Note that our heuristics perform better than the original versions they are built upon.

ETF and ETF-based algorithms’ quality comes with a downside of high theoretical complexity and consequently, slower algorithms due to their dynamic nature. Figure 7b shows runtime performance profiles. As expected, the static BL-EST approach runs much faster than dynamic approaches. DAG-partitioning introduces an overhead to proposed heuristics, but this is still negligible compared to the theoretical complexity of the algorithms. BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO heuristics also perform comparably fast even with partitioning time overhead. ETF and ETF-based heuristics run two to three orders of magnitude slower, making them infeasible to run them on bigger graphs.

c) Big dataset: Table III displays the detailed results on the big dataset, with two processors, for CCR=1 and CCR=20.
(b) CCR=2.5

(d) CCR=3.5

(c) CCR=2.5

Table III: The makespan of BL-EST in absolute numbers, and those of BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO relative to BL-EST on big dataset, when the number of processors \( p \) is 2, and for CCR=\{1,20\}.

Figure 8: Performance profiles on big dataset, with CCR=\{1,5,10,20\}.

Results for CCR=5 and CCR=10 are available in the companion research report [15]. On average, BL-EST-BUSY provides slightly better results than BL-EST-PART. When CCR=1, the heuristics often return a makespan that is slightly larger than the one from BL-EST, on average by 13%, 11%, and 2%, respectively. When CCR=5, BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO provide 20%, 22%, and 29% improvement compared to BL-EST, on average on the whole big dataset when considering an architecture with two processors. When CCR = 10, these values become respectively 42%, 44%, and 49%, and when CCR=20, we obtain 64%, 64%, and 68%.

Figure 8 shows the performance profiles of these four algorithms for CCR=\{1,5,10,20\}. When CCR=1, BL-EST performs best but BL-EST-BUSY performs very close to it. However, when the value of CCR is increasing, it is more and more important to handle communications correctly. We observe that the proposed three heuristics outperform the baseline (BL-EST) as the CCR increases. When CCR=5, in about 90% of all cases, BL-EST-BUSY’s makespan is within 1.5× of the best result, whereas this fraction is only 40% for BL-EST. Starting with CCR=10, the proposed heuristics completely dominate BL-EST algorithm. For all values of CCRs, BL-EST-BUSY outperforms BL-EST-PART. However, BL-EFT-MACRO performs worse than BL-EST-PART and BL-EST-BUSY when CCR=1, and gradually outperforms the other two as the CCR increases.

To understand the nature of datasets where the proposed heuristics and the baseline behave differently, we divided the big dataset into two subsets, the graphs consisting of more than 10% of the nodes as sources, and the ones with less than 10%. Figures 9 and 10 show how the algorithms’ quality differ for these subsets. With a lot of sources (Figure 10), BL-EST
baseline performs badly while BL-EFT-MACRO performs better than with fewer sources. This is due to the inherent nature of DAG-partitioning followed by cluster-by-cluster scheduling. Consider a DAG of clusters with one source cluster. BL-EFT-MACRO would need to schedule all of the nodes in this cluster in one processor to start utilizing any other processor available. When the number of source clusters is high, this heuristic can start efficiently using more processors right from the start.

VI. CONCLUSION

We proposed five new list-based scheduling techniques based on an acyclic partition of the DAGs: ETF-PART, ETF-BUSY, BL-EST-PART, BL-EST-BUSY, and BL-EFT-MACRO. The acyclicity of the partition ensures that we can schedule a part of the partition in its entirety as soon as its input nodes are available. Hence, we have been able to design specific list-based scheduling techniques that would not have been possible without an acyclic partition of the DAG. We compared our scheduling techniques with the widely used BL-EST, ETF, and DSC/GLB-ETF heuristics.

Our experiments suggest that the relative performance of BL-EST-PART and BL-EST-BUSY (ETF-PART and ETF-BUSY) compared to the baseline BL-EST (ETF) does not depend on the number of processors, which means that these heuristics scale well. They provide a steady improvement over the classic BL-EST (ETF) heuristic and they perform even better when the ratio between communication and computation is large. BL-EFT-MACRO seems to not scale when the number of processors increases. Nevertheless, when the ratio between communication and computation is large, it usually outperforms all the other heuristics.

As future work, we plan to consider convex partitioning instead of acyclic partitioning, which we believe will enable more parallelism. The existing clustering techniques in the scheduling area can also be viewed as local algorithms for convex partitioning. To the best of our knowledge, there is no top-down convex partitioning technique available, which we plan to investigate. Also, an adaptation of the proposed heuristics to heterogeneous processing systems would be needed. A difficulty arises in addressing the communication cost, which also requires updating the partitioner.

Acknowledgment: We thank Oliver Sinnen for providing us the Java binaries of their implementation and the datasets they used in their studies [20].
